ABSTRACT

BACKGROUND
Cardiac-resynchronization therapy (CRT) reduces morbidity and mortality in chronic systolic heart failure with a wide QRS complex. Mechanical dyssynchrony also occurs in patients with a narrow QRS complex, which suggests the potential usefulness of CRT in such patients.

METHODS
We conducted a randomized trial involving 115 centers to evaluate the effect of CRT in patients with New York Heart Association class III or IV heart failure, a left ventricular ejection fraction of 35% or less, a QRS duration of less than 130 msec, and echocardiographic evidence of left ventricular dyssynchrony. All patients underwent device implantation and were randomly assigned to have CRT capability turned on or off. The primary efficacy outcome was the composite of death from any cause or first hospitalization for worsening heart failure.

RESULTS
On March 13, 2013, the study was stopped for futility on the recommendation of the data and safety monitoring board. At study closure, the 809 patients who had undergone randomization had been followed for a mean of 19.4 months. The primary outcome occurred in 116 of 404 patients in the CRT group, as compared with 102 of 405 in the control group (28.7% vs. 25.2%; hazard ratio, 1.20; 95% confidence interval [CI], 0.92 to 1.57; P = 0.15). There were 45 deaths in the CRT group and 26 in the control group (11.1% vs. 6.4%; hazard ratio, 1.81; 95% CI, 1.11 to 2.93; P = 0.02).

CONCLUSIONS
In patients with systolic heart failure and a QRS duration of less than 130 msec, CRT does not reduce the rate of death or hospitalization for heart failure and may increase mortality. (Funded by Biotronik and GE Healthcare; EchoCRT ClinicalTrials.gov number, NCT00683696.)
Despite recent advances, heart failure remains a common cause of death and morbidity. According to current guidelines, cardiac-resynchronization therapy (CRT) is indicated for patients receiving stable medical therapy recommended by current guidelines who have moderate-to-severe heart failure, a left ventricular ejection fraction of 35% or less, and a QRS duration of 120 msec or more as assessed electrocardiographically. However, many patients with heart failure have a QRS duration of less than 120 msec; and it is currently not recommended that they receive CRT. Up to 50% of these patients show echocardiographic evidence of ventricular dyssynchrony and hence might benefit from CRT.

Single-center studies have suggested that dyssynchrony criteria that are based on echocardiographic measurements can identify patients who can benefit from CRT, resulting in frequent off-label use of CRT in patients with a narrow QRS complex. Small, randomized clinical studies that were not powered to assess clinically relevant outcomes have suggested the existence of true clinical equipoise, thereby setting the stage for a definitive outcome trial. We therefore initiated the Echocardiography Guided Cardiac Resynchronization Therapy (EchoCRT) study to investigate the effect of CRT on morbidity and mortality among patients with symptomatic heart failure, a narrow QRS complex, and echocardiographic evidence of left ventricular dyssynchrony.

METHODS

STUDY DESIGN AND OVERSIGHT

The EchoCRT study was an investigator-initiated, international, multcenter, randomized clinical trial. The trial was designed by the executive committee (see the Supplementary Appendix, available with the full text of this article at NEJM.org) and sponsored by Biotronik, with support for echocardiographic training and software provided by GE Healthcare. Biotronik was responsible for trial execution and monitoring. The trial protocol, available at NEJM.org, was approved by the institutional review board at each participating center. The study results were analyzed independently at the Robertson Centre for Biostatistics at the University of Glasgow. The first draft of the manuscript was written by the first author, with review by all the authors; there was no commercial involvement in the writing of the article. All the authors made the decision to submit the manuscript for publication. All the authors vouch for the accuracy and completeness of the reported findings and for the fidelity of this report to the trial protocol.

PATIENTS

Eligible patients were 18 years of age or older, with New York Heart Association (NYHA) class III or IV heart failure; a left ventricular ejection fraction of 35% or less; a standard indication for an implantable cardioverter-defibrillator (ICD); stable medical therapy recommended by current guidelines; a QRS duration of less than 130 msec; a left ventricular end-diastolic diameter of 55 mm or more; and echocardiographic evidence of left ventricular dyssynchrony. Dyssynchrony was defined by means of color-coded tissue Doppler imaging as an opposing-wall delay in the peak systolic velocity of 80 msec or more in apical four-chamber or apical long-axis views or by means of speckle-tracking radial strain as a delay in the anteroseptal-to-posterior wall of 130 msec or more in the mid-left ventricular short-axis view. Details of the echocardiographic evaluation of dyssynchrony are provided in the Supplementary Appendix.

Reasons for exclusion included acute decompensated heart failure, intravenous inotropic therapy, atrial fibrillation within the previous month, and bradycardia requiring pacing. Details of the inclusion and exclusion criteria are provided in the Supplementary Appendix. All the patients provided written informed consent.

CRT DEVICE IMPLANTATION

Patients meeting all inclusion criteria and no exclusion criteria underwent implantation of a device with both CRT and ICD capability (CRT-D). Biotronik Lumax HF-T CRT-D systems were used exclusively. All the patients received atrial and right and left ventricular leads. Only transvenous lead systems legally marketed in the respective countries (regardless of manufacturer) were used. Details of device implantation are provided in the Supplementary Appendix. Patients who underwent an unsuccessful attempt at implantation received an ICD rather than a CRT-D and exited the study after enrolling in a 30-day safety registry.

RANDOMIZATION, DEVICE PROGRAMMING, AND FOLLOW-UP

Randomization occurred after successful implantation of the CRT-D system and the adjustment of
1680 Patients were enrolled

825 Were excluded
- 441 Had insufficient dyssynchrony
- 325 Had LVEF >35%
- 50 Were withdrawn by investigator
- 45 Were excluded owing to study closure
- 44 Had baseline NYHA class <III
- 36 Had echocardiographic findings incompatible with study participation
- 34 Withdrew consent
- 22 Had QRS duration ≥130 msec
- 9 Had atrial fibrillation
- 9 Were lost to follow-up
- 7 Had other reasons
- 3 Died

855 Had baseline assessments of:
- QRS duration <130 msec
- Confirmation of LVEF ≤35% by echocardiographic core laboratory
- LVEDD ≥55 mm
- Intraventricular-dyssynchrony inclusion criteria met

34 Underwent unsuccessful CRT-D implantation attempt and were included in 30-day safety registry

821 Underwent successful CRT-D implantation

12 Were withdrawn before randomization

809 Underwent randomization
- 93 Required medication stabilization and second baseline visit before randomization visit

405 Were assigned to control group

404 Were assigned to CRT group

30 Died
- 28 Were withdrawn before study closure
- 6 Were lost to follow-up
- 10 Had ventricular assist device
- 5 Underwent heart transplantation
- 30 Crossed over to CRT
- 7 Died after crossover to CRT

46 Died
- 13 Were withdrawn before study closure
- 5 Were lost to follow-up
- 7 Had ventricular assist device
- 3 Underwent heart transplantation
- 7 Crossed over to control
- 1 Died after crossover to control

Figure 1. Study Enrollment, Randomization, and Follow-up.

At study termination on March 13, 2013, a total of 821 patients had undergone successful implantation of a device for cardiac-resynchronization therapy (CRT) with a defibrillator (CRT-D). A total of 809 patients underwent randomization (404 patients to CRT [CRT capability turned on] and 405 to control [CRT capability turned off]), and follow-up occurred at 1 month and 3 months and then every 3 months thereafter. LVEDD denotes left ventricular end-diastolic diameter, LVEF left ventricular ejection fraction, and NYHA New York Heart Association.
medical therapy for heart failure according to current guidelines. Patients were randomly assigned with the use of a Web-based electronic randomization system in a 1:1 ratio to have CRT capability turned on (the CRT group) or to have CRT capability turned off (the control group). Randomization was based on permuted blocks of four, stratified according to country. After randomization, ICD therapy was programmed on for all patients, and device programming was individualized to maximize the delivery of CRT in the CRT group and to minimize right ventricular pacing in those in the control group (see the Supplementary Appendix).

</table>
After randomization, patients underwent follow-up at 1 month and 3 months and then every 3 months thereafter until the termination of the trial, always with clinical evaluation and device testing and with echocardiography at 6 months and 12 months. Device-implanting physicians were aware of the study-group assignments, but the patients, heart-failure physicians, and study personnel completing the follow-up assessments were unaware of the group assignments.

OUTCOME MEASURES

The primary efficacy outcome was the combination of death from any cause or first hospitalization for worsening heart failure. The primary safety outcome was freedom from complications related to the CRT-D system at 6 months for all patients undergoing an attempted implantation. Detailed definitions of the primary outcome measures are provided in the Supplementary Appendix.

The prespecified secondary outcomes were as follows: all hospitalizations for worsening heart failure throughout the study; changes in NYHA classification after 6 months; changes in quality of life, as measured by the Minnesota Living with Heart Failure questionnaire19 (scores range from 0 to 105, with higher scores indicating worse function, and a clinically significant difference considered to be approximately 5 points) after 6 months; a study-specific score20 based on the composite outcome of death, first hospitalization for worsening heart failure (up to 24 months), and change in the score on the Minnesota Living with Heart Failure questionnaire after 6 months (see the protocol for details); and all-cause mortality.

STATISTICAL ANALYSIS

To detect a 25% reduction in the hazard of a primary outcome with 80% power, we estimated that 381 first primary-outcome events were required. We based our estimate of expected event rates on data from the Cardiac Resynchronization–Heart Failure (CARE-HF) trial,21 with adjustment for the expectation of a lower event rate among patients with a narrow QRS complex, as compared with patients with a wide QRS complex.
complex. We calculated that 1132 patients would accrue the required number of events over an average follow-up of 2.5 years if the final primary event rate in the control group was equal to 38%.

We performed all analyses according to the intention-to-treat principle. Baseline characteristics were summarized as means and standard deviations for continuous variables and as counts and percentages for categorical variables and were compared with the use of two-sample t-tests and chi-square (or Fisher’s exact) tests, respectively. P values for time-to-event analyses were based on log-rank tests (stratified according to country of recruitment) with hazard ratios for treatment effects and 95% confidence intervals calculated from Cox proportional-hazards models that included study group and country of recruitment as covariates. Interactions between treatment effects and subgroup levels were tested for in Cox models that included treatment and subgroup main effects and interaction terms. Time-to-event curves were estimated with the use of the Kaplan–Meier method.

Changes in NYHA class from baseline to 6 months were analyzed as a binary outcome (improved condition vs. no change or deteriorated condition) with the use of a logistic-regression model with adjustment for country of recruitment, providing odds ratios for improvement and corresponding 95% confidence intervals. The change in total score on the Minnesota Living with Heart Failure questionnaire (defined as the score at 6 months minus the score at baseline) was analyzed with the use of an analysis of covariance with adjustment for the baseline total score and country of recruitment, and adjusted mean differences between study groups and 95% confidence intervals were calculated. All P values in the efficacy analysis were two-sided.

The analysis of the primary safety outcome aimed to exclude a complication-free rate of 70% or less, on the basis of an exact one-sided binomial proportion test to show that the CRT-D system had similar complication-free rates as previously reported for comparable studies.22,23

RESULTS

PATIENT ENROLLMENT AND FOLLOW-UP

Beginning in August 2008, patients were enrolled at 115 centers in the United States, Canada, Israel, Australia, and Europe. On March 13, 2013, enrollment was stopped by the executive committee on the recommendation of the independent data and safety monitoring board, on the basis of futility with a potential for harm. No follow-up data were included after the study-closure date. A final clinical-status assessment and final device reprogramming to turn off CRT capability were conducted, when possible, and patients were subsequently returned to standard care.

At study termination, 1680 patients had consented to trial participation, and 809 had undergone randomization (404 patients to CRT and 405 to control) (Fig. 1). A total of 825 patients were excluded before implantation, the majority of whom did not meet the echocardiographic inclusion criteria according to either the local site or the core laboratory (602 patients). The echocardiographic core laboratory agreed with the findings of the local sites regarding dyssynchrony in 89.3% of the patients, excluding 10.7% whose degree of dyssynchrony could not be confidently confirmed. An additional 34 patients were excluded owing to unsuccessful implantation of a CRT-D (as described in the Supplementary Appendix), and 12 withdrew from the study before randomization.

The mean follow-up period was 19.4 months for all patients and 19.8 months for surviving patients. The study-visit compliance rate among patients was 95.5%; a total of 5324 of the 5575 required study visits were completed up to the date of patient withdrawal from the study. Details regarding patient withdrawal, loss to follow-up, and crossovers are provided in the Supplementary Appendix.

CHARACTERISTICS OF THE PATIENTS AT BASELINE

The baseline characteristics of the patients who underwent randomization are shown in Table 1, and Table S1 in the Supplementary Appendix. These characteristics were similar in the two groups, although chronic kidney disease was more prevalent in the CRT group. The mean QRS duration measured by the centers was 105.0 msec for the CRT group and 105.4 msec for the control group. The QRS width at baseline was independently measured at the electrocardiographic core laboratory and was repeated for crossover approval. The mean left ventricular ejection fraction and variables regarding left ventricular dyssynchrony did not differ significantly between the two groups.
**Efficacy Outcomes**

The primary outcome, death from any cause or hospitalization for worsening heart failure, occurred in 116 of 404 patients (28.7%) in the CRT group, as compared with 102 of 405 (25.2%) in the control group (hazard ratio with CRT, 1.20; 95% confidence interval [CI], 0.92 to 1.57; \( P = 0.15 \)) (Table 2 and Fig. 2). During the trial, 45 of 404 patients (11.1%) in the CRT group died, as compared with 26 of 405 (6.4%) in the control group (hazard ratio, 1.81; 95% CI, 1.11 to 2.93; \( P = 0.02 \)) (Table 2). Table S2 in the Supplementary Appendix shows the causes of death, as originally adjudicated. There was an excess of deaths due to cardiovascular causes in patients randomly assigned to CRT (37 deaths, vs. 17 in the control group; \( P = 0.004 \)).

Of 809 patients, 418 (51.7%) were hospitalized at least once during follow-up (224 patients in the CRT group vs. 194 in the control group). Most of these hospitalizations were for cardiovascular reasons (147 patients in the CRT group vs. 137 in the control group; hazard ratio, 1.11; 95% CI, 0.88 to 1.40; \( P = 0.36 \)). The hospitalization rate for worsening heart failure did not differ significantly between the two groups (Table 2). A total of 229 hospital admissions for heart failure (35.6 admissions per 100 years of follow-up) occurred in the CRT group, as compared with 181 (27.6 per 100 years of follow-up) in the control group.

Changes from baseline to 6 months with respect to NYHA class and score on the Minnesota Living with Heart Failure questionnaire did not differ significantly between the study groups. There was also no difference between groups in the composite-outcome score that included death, first hospitalization for worsening heart failure, and change in score on the Minnesota Living with Heart Failure questionnaire. The details of these results are shown in Table S3 in the Supplementary Appendix.

**Subgroups**

The effects of treatment on nine prespecified subgroups for the primary composite outcome and the component outcomes are shown in Figures S1A, S1B, and S1C in the Supplementary Appendix. There were no significant treatment-by-subgroup interactions for the primary outcome.

In the EchoCRT study, the use of CRT did not reduce
nally significant treatment-by-subgroup inter-
the rate of death from any cause or first hospital-
action that suggested a greater harm with CRT in
ization for heart failure among patients with symp-
patients less than 65 years of age (Fig. S1C in the
matic heart failure, a left ventricular ejection frac-
Supplementary Appendix) (P = 0.02 for interaction).
tion of 35% or less, and a QRS duration of less than

SAFETY

The rate of freedom from complications related to
the CRT-D system at 6 months was 89.6% for the
population that included all patients who underwent
an attempted implantation (binomial proportion,
0.90; 95% CI, 0.87 to 0.92; P < 0.001 for excluding
a rate ≤70%). A total of 50 patients (12.4%) in the
CRT group had complications, as compared with
36 (8.9%) in the control group (P = 0.11).

A total of 93 serious adverse events related to
the device or implantation occurred in 70 of the
404 patients in the CRT group, and 50 such events
occurred in 45 of the 405 patients in the control
group (P = 0.01) (Table 3). A total of 74 device-
related serious adverse events after implantation
occurred in 55 patients (13.6%) in the CRT
group, and 32 events in 29 patients (7.2%) in the
control group (P = 0.003). This difference was largely driven
by a difference of a factor of approximately three in
the number of lead-related serious adverse events
between the CRT and control groups (68 vs. 22).
These events included dislodgement of the left
ventricular lead in 14 patients (3.5%) in the CRT

group and in 4 (1.0%) in the control group.
Rates of implantation-related serious adverse
events were similar between the two groups
(19 events in 17 patients [4.2%] in the CRT
group and 18 events in 16 patients [4.0%] in the
control group).

The total number of patients receiving an ICD
shock was similar between the study groups (oc-
curring in 76 [18.8%] and 63 [15.6%] patients in
the CRT and control groups, respectively). Inap-
propriate shocks were more prevalent in patients
in the CRT group than in those in the control
group (20 patients [5.0%] vs. 7 [1.7%], P = 0.01).

DISCUSSION

In the EchoCRT study, the use of CRT did not reduce
the rate of death from any cause or first hospital-
ization for heart failure among patients with symp-
omatic heart failure, a left ventricular ejection frac-
tion of 35% or less, and a QRS duration of less than
130 msec. The observed excess mortality with CRT
in this trial is of clinical concern. The excess mor-
tality was due to a significant increase in the rate of
death from cardiovascular causes among patients
receiving CRT. There was a nonsignificant trend
toward an increase in mortality related to heart
failure, which was paralleled by a nonsignificant
increase in hospitalization for heart failure. How-
ever, the interpretation of secondary outcomes in
trials that fail to confirm the primary hypothesized
outcome should be approached with great caution.
Mechanical dyssynchrony in our study was
systematically assessed with the use of uniform
equipment and a core laboratory. In addition, advanced echocardiographic techniques were used to assess dyssynchrony, including tissue Doppler imaging and speckle-tracking radial strain, which have been associated with outcome when the QRS complex is wide. Our results reinforce the notion that, at least until new methods of assessment are developed, QRS width (with or without mechanical dyssynchrony) remains the primary determinant of response to CRT.

Clinical-outcome trials may not be appropriately designed to elucidate the mechanisms of benefit or harm associated with a therapeutic intervention. However, they may provide insights that inform future research. Since CRT-induced proarrhythmia in patients with a narrow QRS complex could account in part for the increased mortality among patients randomly assigned to active therapy in this study, the numbers of appropriate and inappropriate ICD shocks were analyzed, both of which may contribute to an increase in mortality among patients who received an ICD or CRT-D. Although the total number of patients receiving an ICD shock was similar between the study groups, inappropriate shocks were more prevalent in patients in the CRT group than in those in the control group. Since unnecessary pacing may contribute to the development of heart failure, it is of note that ventricular pacing in the control group was negligible in this study. Patients with ischemic cardiomyopathy or suboptimal placement of the

* Data for subcategories with an incidence of less than 3.0% are not shown. Patients could have more than one event. CRT-D denotes cardiac-resynchronization device with defibrillator, and ICD implantable cardioverter–defibrillator.
left ventricular lead may be at greater risk for arrhythmic events with CRT, but subgroup analyses did not show evidence of any interactions between these factors and clinical outcomes. Although interactions of the location of the left ventricular lead with respect to activation or scar have not been examined, it is possible that this study did not show a benefit because the lead placement was not tailored to the mechanical abnormal substrate of patients with heart failure and normal or near-normal QRS duration or because the leads were placed in scar areas.\(^{28,29}\)

Current guidelines do not recommend CRT for patients with a normal QRS duration.\(^1\) The mean QRS width in the CARE-HF\(^22\) trial was 160 msec, and the majority of patients included in many other major trials have had a QRS duration of more than 150 msec.\(^{23,30,31}\) A recent meta-analysis evaluating the effect of QRS duration on the efficacy of CRT showed that CRT significantly reduced the rate of death from any cause or hospitalization among patients with a QRS duration of 150 msec or more, but the magnitude of effect and the certainty of benefit declined with shorter QRS duration.\(^{32}\)

The excess risk of CRT among patients included in the EchoCRT study who had heart failure and a narrow QRS complex is of particular concern, because it serves as a reminder that the implantation of left ventricular leads and the ongoing care of patients treated with CRT (which may involve subsequent manipulation of the leads for improvement in pacing) are not without challenges. Indeed, the rate of adverse events after device implantation was significantly higher among patients in the CRT group than among those in the control group, a difference driven largely by a difference of a factor of three in the number of lead-related serious adverse events between the two groups.

In conclusion, we investigated the potential benefit of CRT-D in patients with systolic heart failure and a QRS duration of less than 130 msec. As compared with an ICD with inactivated CRT, a CRT-D did not reduce the rate of death from any cause or hospitalization for heart failure and may increase mortality among these patients.
